Abstract

Contrastive learning has become a successful approach for learning powerful text and image representations in a self-supervised manner. Contrastive frameworks learn to distinguish between representations coming from augmentations of the same data point (*positive* pairs) and those of other (*negative*) examples. Recent studies aim at extending methods from contrastive learning to graph data. In this work, we propose a general framework for learning node representations in a self supervised manner called Graph Contrastive Learning (GraphCL). It learns node embeddings by maximizing the similarity between the nodes representations of two randomly perturbed versions of the same graph. We use graph neural networks to produce two representations of the same node and leverage a contrastive learning loss to maximize agreement between them. We investigate different standard and new negative sampling strategies as well as a comparison without negative sampling approach. We demonstrate that our approach significantly outperforms the state-of-the-art in unsupervised learning on a number of node classification benchmarks in both transductive and inductive learning setups.

Key words: Graph Neural Network, Contrastive Learning, Self-Supervised Learning, Node Classification.

1. Introduction

In many fields, the rapid increase in data volume and the complexity of its structure/representation make it difficult to exploit it effectively. Graphs offer a unified framework for aligning well-structured and unstructured data. However, graphs have long been poorly leveraged because of their complexity, and limited approaches relying on content associated with nodes and links. Recently, graph representation learning has attracted the attention of the scientific community as a way of analysing graphs and helping to exploit the richness of information that resides in poor-structured data. Graphs are characterized by a set of nodes, which represent the entities, and a set of links connecting them, representing relationships between the nodes. Nodes may be of different types, and may further be associated with several features. And links may represent different relationships and may also be associated with different attributes or semantic content. One of the major challenges facing graph representation learning is learning node embeddings which capture both node features and graph structure. These representations can then be fed into downstream machine learning models.

Most successful approaches for graph representation have been great efforts to generalize neural networks to graph data and fall under the umbrella of Graph Neural Networks (GNNs) or Deep Geometric Learning [1–4]. These approaches have achieved remarkable results in a number of important tasks such as node classification [5–7] and link prediction [8, 9]. However, these methods are very reliant on human annotation and suffer from the necessity of some form of supervision. This requires high cost, expert knowledge in the domain and the use of annotated data, which is not often available. Hence, it is of importance to develop methods capable of learning representations in an unsupervised manner.

In order to compensate for the absence of labels or predefined tasks, some unsupervised methods have adopted the homophily hypothesis, which states that linked nodes should be nearby in the embedding space [10]. Inspired by the Skipgram algorithm for embedding words into a latent space, where adjacent vectors correspond to co-occurring words in a sentence [11], a majority of

1
2
3
4
5
6
7
8
9 these methods use random walks to generate sentence-like sequences where co-
10 occurring nodes are close to one another in the embedding space [12, 13] and
11 can also be adapted to heterogeneous graphs [14–16]. Other methods, such as
12 autoencoders, also employ the homophily hypothesis by reconstructing either
13 the adjacency matrix or the neighborhood of a node [8, 17]. Despite their suc-
14 35 cess in learning relatively powerful representations, relying on the homophily
15 hypothesis may bias these methods towards emphasizing the direct proximity
16 of nodes over topological information [17]. More recently, [18] proposed Deep
17 Graph Infomax (DGI) that learns representations by training a discriminator
18 to distinguish between representations of nodes that belong to the graph from
19 nodes that belong to a corrupted graph. Leveraging recent advances in unsu-
20 pervised visual representations [19], the success of DGI has been attributed to
21 the maximization of mutual information between global and local parts of the
22 input. This requires learning global representations of the entire graph which
23 40 can be very costly and even intractable when dealing with large graphs.

24
25
26
27
28
29
30
31
32 To overcome the above-mentioned challenges, we here propose a contrastive
33 framework for self-supervised learning of nodes’ representations, called GraphCL.
34 We take inspiration from the success of contrastive losses in learning meaning-
35 ful representations of images [20, 21] and develop a model that learns node
36 embeddings by maximizing the similarity between the representations of two
37 50 randomly perturbed versions (views) of the intrinsic features and link structure
38 of the same node’s local subgraph. The perturbation consists of randomly drop-
39 ping from its L -hop subgraph, a subset of edges and nodes’ intrinsic features.
40 Other researchers have also used the contrastive loss to learn nodes or graph
41 representations using different augmentation (perturbation) strategies. In [22],
42 55 the authors used the diffusion matrix as a second view of the graph. In [23], the
43 authors used four different strategies consisting of dropping nodes, perturbing
44 edges, masking attributes or sampling subgraphs.

45
46
47
48
49
50
51
52
53 Contrastive learning is a special case of Siamese networks, which are weight-
54 sharing neural networks applied to two or multiple inputs. Recent approaches
55 60 use augmentations of the same data point as inputs and maximize the similarity
56
57
58

1
2
3
4
5
6
7
8
9 between the learned representations of the two inputs. Maximizing the similar-
10 ity between each pair of augmented data points in the dataset can lead to a
11 trivial solution. Since we want representations of all pairs of augmented views
12 to be equal, a possible solution is to map all nodes to a single point (representa-
13 tion). This is what we call a collapsing of representations to a single data
14 point (i.e. if all representations are the same, then so are those of each pair
15 of augmented views). Contrastive learning is one way of preventing this unde-
16 sirable solution. It does so by contrasting between *positive* (similar) examples
17 and *negative* (dissimilar) examples. The objective of the training phase is to
18 map positive examples to nearby locations in the destination (representation)
19 space while pushing away negative examples often by using *noise-contrastive*
20 *estimation* [24]. One key component of contrastive learning frameworks is the
21 choice of negative examples. The most common strategy is to uniformly sample
22 from the training dataset using examples either from the current batch or from a
23 memory bank. It has been shown that these approaches require large batches or
24 memory banks to perform well for visual representation [20, 21]. To improve the
25 performance and efficiency of contrastive frameworks, recent studies have pro-
26 posed novel sampling strategies. Most strategies are based on the assumption
27 that hard negative examples (i.e. examples that are hard to distinguish from a
28 positive pair) are beneficial in learning more powerful representations. In [25],
29 authors use hard negative mixing to synthesize new examples from the available
30 hard negatives. In [26], the authors sample negatives from a *ring* around each
31 positive (i.e. they sample negatives that are neither too close nor too far from
32 the positive example).

38
39
40
41
42
43
44
45
46

47 More recent Siamese network architectures preventing representation collaps-
48 ing still rely on the use of pairs of positive examples only. In [27], the authors
49 experimentally show that the learned representations of their proposed frame-
50 work do not collapse when using a momentum network even when not using
51 negative examples. In [28], the authors avoid the collapsing phenomenon by
52 simply using a stop-gradient strategy when directly maximizing the similarity
53 between two augmented views. The stop-gradient strategy consists of consid-

9 ering the representation of one of the augmented views as a constant when
10 updating the network parameters.

11
12 While these methods have shown surprisingly good results when applied
13 to image datasets, it is not clear whether they are easily generalizable to non-
14 Euclidean data such as graphs. In this work, we introduce novel sampling
15 strategies of negative examples based on the graph structure and show that
16 our approach improves the performance of the learned representations on down-
17 stream classification tasks and outperforms existing methods. In addition, we
18 conduct extensive experiments to study the different components of our Siamese
19 network-based approach for learning nodes' representations which enable us to
20 answer the following questions:
21
22

- 23 • Is a larger set of negative examples always useful in learning good repre-
24 sentations?
25
- 26 • Does sampling hard negative examples improve the quality of the repre-
27 sentation?
28
- 29 • Can we train a Siamese neural network to learn nodes' representations
30 without using negative examples?

39 **2. Background**

40 *2.1. Problem formulation.*

41
42 Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an undirected graph where \mathcal{V} is a set of nodes and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$
43 is a set of edges. Each node $u \in \mathcal{V}$ is represented by a feature vector $x_u \in \mathbb{R}^P$.
44 An adjacency matrix $A \in \mathbb{R}^{N \times N}$ represents the topological structure of the
45 graph where $N = |\mathcal{V}|$ is the number of nodes in the graph. Without loss of
46 generality we assume the graphs to be unweighted i.e $A_{u,v} = 1$ if $(u, v) \in \mathcal{E}$
47 and $A_{u,v} = 0$ otherwise. We are also provided with a matrix $X \in \mathbb{R}^{N \times P}$ that
48 summarizes the intrinsic feature vectors of all nodes.
49

50
51 Our objective is to learn an effective representation of nodes without human
52 annotation. This will be done through the learning of a graph neural network
53
54
55
56
57

1
2
3
4
5
6
7
8
9 encoder f that maps both node original feature and the graph structure to
10 a higher level representation i.e. $f(X, A) = H^{(L)} \in \mathbb{R}^{N \times P'}$, where P' is the
11 embedding size. The u -th row of $H^{(L)}$ corresponds to the embedding $h_u^{(L)}$ of
12 node u . In the remainder of the paper, h_u refers to the output of the GNN's
13 last layer, i.e. $h_u = h_u^{(L)}$.
14
15
16
17

18 2.2. Graph Neural Networks (GNNs).

19 GNNs are a class of graph embedding architectures which use the graph
20 structure in addition to node and edge features to generate a representation
21 vector (i.e., embedding) for each node. Recent GNNs learn node representations
22 by aggregating the features of neighboring nodes and edges. The output of the
23 l -th layer of these GNNs is generally expressed as
24
25
26
27

$$28 \quad h_u^{(l)} = \text{COMBINE}^{(l)}(h_u^{(l-1)}, \text{AGGREGATE}^{(l)}(\{(h_u^{(l-1)}, h_v^{(l-1)}) : v \in \mathcal{N}(u)\})),$$

29
30 (1)

31 where $h_u^{(l)}$ is the feature vector of node u at the l -th layer initialized by $h_u^{(0)} = x_u$
32 and $\mathcal{N}(u)$ is the set of first-order neighbors of node u . According to Eq. (1),
33 $h_u^{(L)}$ corresponds to the output of the last layer of the GNN, which involves the
34 nodes of node u 's L -hop subgraph. Different GNNs use different formulations
35 of the COMBINE and AGGREGATE functions; the ones used in this work are
36 described in subsection 4.1.3.
37
38
39
40

41 2.3. Contrastive learning

42 In this work, we consider the dictionary look up formulation of contrastive
43 learning, which means that considering a query h_q , a corresponding positive pair
44 h_q^+ and a set of negative examples Q_q^- , a contrastive loss is a function which
45 has a low value when h_q is similar to h_q^+ and dissimilar to all elements of Q_q^- .
46 A successful and widely used form of contrastive loss is defined as:
47
48
49
50

$$51 \quad \mathcal{L}_{h_q, h_q^+, Q_q^-} = -\log \frac{\exp(h_q^\top h_q^+ / \tau)}{\exp(h_q^\top h_q^+ / \tau) + \sum_{h_n \in Q_q^-} \exp(h_q^\top h_n / \tau)}, \quad (2)$$

52 where τ is a temperature hyperparameter and h_q , h_q^+ and all h_n in Q_q^- are
53 L_2 normalized feature vectors. The final loss is summed across all queries q
54
55
56
57
58

belonging to the dataset \mathcal{D} and can be expressed as follows when scaled by the temperature τ [29]:

$$\mathcal{L} = -\frac{1}{\tau|\mathcal{D}|} \sum_{q \in \mathcal{D}} h_q^\top h_q^+ + \frac{1}{|\mathcal{D}|} \log \sum_{q \in \mathcal{D}} \left(\exp(h_q^\top h_q^+ / \tau) + \sum_{h_n \in Q_q^-} \exp(h_q^\top h_n / \tau) \right), \quad (3)$$

where $|\mathcal{D}|$ is the number of elements in \mathcal{D} .

135 In Contrastive learning framework,, different negative sampling strategies (i.e., the way to build Q_q^-) may be employed to avoid collapsing of the contrastive loss optimization problem into a unique representation of all samples.

2.4. Simple Siamese neural networks for nodes representation

In [28], the authors argue that their approach can prevent collapsing when maximizing the similarities between the representations of two views of the same image without the use of negative examples. Their approach works by sampling two views of x_1 and x_2 of the same image x which they process using an encoder f and a multi-layer perceptron (MLP) prediction head g . Letting $p_1 = g(f(x_1))$, $p_2 = g(f(x_2))$, $h_1 = f(x_1)$ and $h_2 = f(x_2)$ denote respectively the outputs of the MLP prediction and the encoder, the objective is to minimize the symmetric negative cosine similarity loss which is defined as:

$$\mathcal{L} = \frac{1}{2}S(p_1, \text{stopgrad}(h_2)) + \frac{1}{2}S(p_2, \text{stopgrad}(h_1)), \quad (4)$$

where $S(p_1, h_2) = -\frac{p_1}{\|p_1\|} \cdot \frac{h_2}{\|h_2\|}$ and the stopgrad operation consists of treating h_2 , respectively h_1 , as constant when updating the models' parameters.

3. Methodology of the proposed approach

3.1. GraphCL

GraphCL's objective is to learn node representations by maximizing the similarity between two embeddings of the same node. The two embeddings are obtained from applying a GNN encoder to two perturbed versions of the graph. This framework has three main components: a stochastic perturbation, a GNN

1
2
3
4
5
6
7
8
9 based encoder and a contrastive loss function. We first introduce each of these
10 components, and then give a high-level overview of the proposed method.
11

- 12 • **Stochastic perturbation.** We apply two stochastic perturbations to the
13 graph which allow us to obtain two representations of the same node which
14 150 graph which allow us to obtain two representations of the same node which
15 we consider as positive examples. In this work, we consider simultaneous
16 transformations of both node features and the connectivity of the graph.
17 The graph structure is transformed by randomly dropping edges using
18 samples from a Bernoulli distribution. For the node’s original features, we
19 apply a similar strategy by simply applying dropout to the input features;
20 21 22 155 apply a similar strategy by simply applying dropout to the input features;
23
- 24 • **Graph neural network encoder.** We apply a GNN based encoder
25 that learns representations of all nodes in the graph. Our framework
26 supports several choices of GNN architectures. Details about the choices
27 of architectures are given in section 4.1.3.
28
- 29 • **Contrastive loss function.** We define a *pretext* prediction task that
30 31 160 aims at identifying the corresponding positive example h_q^+ of a representa-
32 tion h_q given a set of generated examples, with h_q and h_q^+ being a positive
33 pair of examples (i.e. obtained from the GNN representations of two trans-
34 formations of the graph). As for the negative examples generation, details
35 are provided in subsection 3.2.
36 37 38 165 are provided in subsection 3.2.
39
40

41 3.2. Negative sampling strategies

42 Negative sampling has been shown to be a key ingredient for the success
43 of contrastive learning frameworks. Different strategies have been proposed to
44 build negatives examples for visual presentations [20, 21, 25, 26]. First, we inves-
45 tigate whether the conclusions that have been drawn from the most successful
46 approaches of visual representations are still valid when applied to graphs. We
47 hereafter introduce three negative sampling strategies: the two first are standard
48 170 while the third one is new and well adapted to graph.
49
50

- 51 • **Random sampling.** This approach consists of considering the samples of
52 the current (randomly generated) mini-batch as negatives. The problem
53 175

with this approach is the number of negative examples is limited by the size of the mini-batch which is limited by the memory of the GPU. An alternative would be to randomly sample negatives from a memory bank that contains either representations of the whole training set or a queue with representations of the last few batches.

180

- **Feature-based sampling.** In [26], the authors propose to pick two percentiles ω_k and $\omega_l \in [0, 100]$ and considering h_{n_c} as a negative example for a representation of a query h_q if and only if $h_q^\top h_{n_c}$ is within the ω_k -th to the ω_l -th percentile of all $h_n \in Q_q^-$. This enables to build easily hard negative examples (i.e., negatives that are hard to distinguish from the current sample) which are beneficial in learning powerful representations as mentioned in [30, 31]. To adapt this method to the graph setting, instead of considering the similarities in the representation space, which requires using the encoder to learn the representations of all nodes in the graph, we simply consider the similarities of the nodes' original features. For each node u , we consider as negatives all nodes v whose original features are neither too close nor too far from those of node u (i.e. $x_u^\top x_v / \|x_u\| \|x_v\|$ is within the ω_k -th to the ω_l -th percentile of all nodes of the graph).

190

- **Graph-based sampling.** Using original feature similarities as a negative sampling strategy requires computing similarities between each pair of nodes in the graph then sorting them and fine tuning the model to select the best values for the percentiles ω_k and ω_l . To avoid this, we propose to make use of the graph structure information to select negatives. Instead of considering distances between the nodes' original features, we use the distance between the nodes on the graph. For each node u , we simply sample negatives from its l -th order neighbors.

200

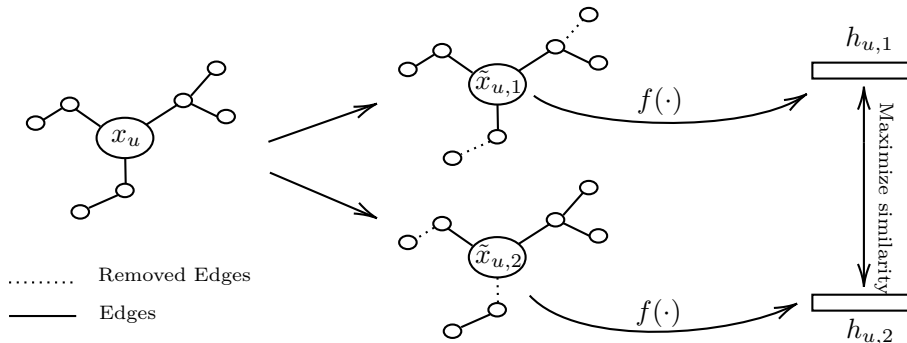

Figure 1: A high-level overview of our method for a subgraph around node u . $h_{u,1}$ and $h_{u,2}$ form a positive pair with a query $h_q = h_{u,1}$ and its corresponding key $h_q^+ = h_{u,2}$.

3.3. Overview of GraphCL

The training algorithm of GraphCL is summarized in the following steps:

1. Draw two stochastic perturbations t_1 and t_2 as defined in section 3.1 and illustrated in Figure 1. Apply them to nodes' original features and the graph structure:

- $(\tilde{X}_1, \tilde{A}_1) \sim t_1(X, A)$
- $(\tilde{X}_2, \tilde{A}_2) \sim t_2(X, A)$

2. Apply the encoder to both views of the graph:

- $H_1^L = f(\tilde{X}_1, \tilde{A}_1)$
- $H_2^L = f(\tilde{X}_2, \tilde{A}_2)$

3. Select negative examples as suggested in subsection 3.2.
4. Update parameters of the encoder f using the loss function defined in Eq. (3).

3.4. Extension to inductive setup

Unlike the transductive setup where we have access to the whole graph and features of all nodes of the graph during training time. In the inductive setup, the objective is to generate representations of nodes that were not used when training the model. These previously unseen nodes can be new nodes in an

1
2
3
4
5
6
7
8
9
220 evolving graph such as a social network, we refer to this by the single graph
10 inductive setup. These nodes can also come from previously unseen graphs
11 which helps generalization across graphs with the same form of features, we
12 refer to this by the multiple graph inductive setup.
13
14

15 GraphCL can be easily extended to both setups. The extension to the multi-
16
225 ple graph setup is straightforward, as it consists of training the encoder on each
17 of the available graphs for the training and using the learnt encoder to produce
18 representations of nodes of the new graphs. For inductive learning on large
19 graphs, we train the encoder by sampling minibatches of nodes. The training
20 algorithm of GraphCL for the inductive setup is summarized in the following
21 steps for each sampled minibatch \mathcal{B} :
22
23
24
25 230

26
27 1. For each node u in the minibatch we define (X_u, A_u) as the subgraph
28 containing all nodes and edges that are at most L -hops from u in the
29 graph and their corresponding features;
30

31
32 2. Draw two stochastic perturbations t_1 and t_2 as defined in section 3.1 and
33 apply them to u 's L -hop neighborhood subgraph:
34
235

- 35 • $(\tilde{X}_{u,1}, \tilde{A}_{u,1}) \sim t_1(X_u, A_u)$
- 36 • $(\tilde{X}_{u,2}, \tilde{A}_{u,2}) \sim t_2(X_u, A_u)$

37
38
39 3. Apply the encoder to the two representations of node u :

- 40 • $h_{u,1} = f(\tilde{X}_{u,1}, \tilde{A}_{u,1})$
- 41 • $h_{u,2} = f(\tilde{X}_{u,2}, \tilde{A}_{u,2})$

42
43 240 4. Update parameters of the encoder.
44
45
46
47

48 **4. Experiments**

49
50 We evaluate the effectiveness of GraphCL representations on both transduc-
51 tive and inductive learning setups. The transductive learning setup consists
52 of embedding nodes from a fixed graph (i.e. all node features and the entire
53 245 graph structure are known during training time). On the other hand, the induc-
54 tive learning setup consists of generating representation of unseen nodes or new
55

9 graphs. Following common practice, we opt for a linear evaluation of the learned
10 node representations. Specifically, we use these representations to train a logistic
11 regression model to solve multiclass node classification tasks on five well-know
12 250 benchmark datasets, three for the transductive learning setup and two for the
13 inductive setup. We summarize the datasets and the baselines respectively in
14 sections 4.1.1 and 4.1.2, provide model configuration and implementation details
15 in section 4.1.3, and discuss the results in section 4.2.
16
17
18
19
20

21 255 *4.1. Experimental setup*

22 *4.1.1. Datasets*

23
24 For the transductive setting, we utilize Cora, Citeseer and Pubmed [32],
25 three citation networks where nodes are bag of words representations of docu-
26 ments and edges correspond to (undirected) citations. Each node belongs to one
27 class. We also use ogbn-arxiv, which is another citation network, where nodes
28 260 are computer science papers represented by a 128-dimensional feature vector
29 obtained by averaging the embeddings of words in its title and abstract. Each
30 node belongs to one of forty subject areas of arXiv CS papers [33].
31
32
33
34

35
36 On the other hand, a protein-protein interaction dataset (PPI) is used for
37 265 the inductive setting on multiple graphs [34]. It consists of multiple graphs
38 corresponding to different human tissues where node features are the positional
39 gene sets, motif gene sets and immunological signatures. Each node has several
40 labels among 121 labels from the gene ontology. For the inductive setting on
41 large graphs, we use a Reddit dataset [5]. It represents a large social network
42 where nodes correspond to Reddit posts (i.e. represented by their GloVe embed-
43 ding [35]) and edges connecting two posts mean that the same user commented
44 270 on them. Labels are the posts' *subreddit* and the objective is to predict the
45 community structure of the social network.

Table 1: Description of datasets

on those published in 2018, and test on those published since 2019.

4.1.2. Baselines

For the transductive learning tasks, we use four unsupervised methods for comparison: Label Propagation (LP) [37], DeepWalk [12], Embedding Propagation (EP-B) [38], and Deep Graph Infomax (DGI) [18]. We also report the results of training logistic regression on the intrinsic input features only, and also on the concatenation of DeepWalk embeddings and the nodes’ intrinsic features. Aside from unsupervised methods, we also compare our approach to strong supervised baselines, Graph Convolution Networks (GCN) [2].

For the inductive learning tasks, in addition to DeepWalk and DGI, we compare GraphCL with the unsupervised GraphSAGE methods [5]. We also provide results of two supervised approaches, FastGCN [39] and Gated Attention Networks (GaAN) [40].

4.1.3. Model configurations

Eq. (1) provides a general formulation of graph neural networks. Several architectures have been proposed for the choice of *AGGREGATE* and *COMBINE*. In all our experiments the basic update rule is the mean pooling variant from [5].

$$h_u^{(l)} \leftarrow \left(W^{(l-1)}\right)^\top \cdot \text{MEAN}(\{h_u^{(l-1)}\} \cup \{h_v^{(l-1)}, \forall v \in \mathcal{N}(u)\}), \quad (5)$$

where the *MEAN* operator is the element-wise mean of all vectors in $(\{h_u^{(l-1)}\} \cup \{h_v^{(l-1)}, \forall v \in \mathcal{N}(u)\})$, and $W^{(0)} \in \mathbb{R}^{P \times P'}$ and $W^{(l-1)} \in \mathbb{R}^{P' \times P'}$, for $l > 1$, are

learnable linear transformations.

All GNN aggregation operations are computed in parallel resulting in a matrix representation as follows:

$$H^{(l)} = \hat{A}H^{(l-1)}W^{(l-1)} \quad (6)$$

where $H^{(l)} = [h_1^{(l)}, h_2^{(l)}, \dots, h_N^{(l)}]^\top$ is the matrix of nodes' hidden feature vectors at the l -th layer and $\hat{A} = \check{D}^{-1}\check{A}$ is the normalized version of the adjacency matrix with added self-loop $\check{A} = A + I_N$ with \check{D} being its diagonal degree matrix, i.e. $\check{D}_{ii} = \sum_j \check{A}_{ij}$. We also consider the symmetrically normalized version of the adjacency matrix where $\hat{A} = \check{D}^{-\frac{1}{2}}\check{A}\check{D}^{\frac{1}{2}}$. We refer to encoders using this variant by GCN when needed.

Transductive learning. For Citeseer and Pubmed, we use a one layer GNN as defined in Eq. (6), the encoder is then simply expressed as:

$$f(X, A) = \hat{A}XW^{(0)} \quad (7)$$

For Cora, our encoder is a two-layer GNN:

$$f(X, A) = \hat{A}\sigma(\hat{A}XW^{(0)})W^{(1)} \quad (8)$$

where σ is an exponential linear unit [41], and $f(X, A)$ is the concatenation of all nodes' embeddings. In each layer, we compute $P' = 512$ features resulting in a node embedding size of 512. For the larger ogbn-arxiv dataset, we use a three-layer GNN, and train the model by randomly sampling 1024 negative examples for each node.

Inductive learning. For both inductive learning setups on large graphs and on multiple graphs, we use a three-layer mean-pooling encoder with residual units as follows:

$$H^{(1)} = \sigma(\hat{A}XW_1^{(0)} + XW_2^{(0)}) \quad (9)$$

$$H^{(2)} = \sigma(\hat{A}H^{(1)}W_1^{(1)} + H^{(1)}W_2^{(1)}) \quad (10)$$

$$f(X, A) = \hat{A}H^{(2)}W_1^{(2)} + H^{(2)}W_2^{(2)} \quad (11)$$

We set the hidden layers and the embedding size to $P' = 512$ and apply RELU as an activation function.

For the multiple-graph setting, we sample one graph at a time from the training set to train the contrastive loss function. For the single graph inductive setup, the scale of the dataset makes it impossible to fit into GPU memory. We therefore adopt the sub-sampling strategy of [5]. We first select a minibatch of nodes and construct for each of them their L -hop neighborhood subgraph by sampling a fixed size neighborhood. We sample 10 nodes in each of the three levels resulting in $1 + 10 + 100 + 1000 = 1111$ neighboring nodes .

We use Pytorch [42] and the Pytorch Geometric [43] libraries to implement all our experiments. We initialize all models using Glorot initialization [44] and trained them to minimize the contrastive loss provided in Eq. (3) using the Adam optimizer [45] with an initial learning rate of 0.001. We tune the weight decay in $\{0.001, 0.01, 0.05, 0.1, 0.15\}$. We further tune the temperature τ in the loss function in $\{0.1, 0.5, 0.8, 1.0\}$ and the number of epochs in $\{20, 50, 100, 150, 200\}$.

To define the stochastic perturbation, we tune the probability of dropping an edge in $[0.05, 0.75]$ and the probability of dropping node features in $[0.2, 0.8]$. GraphCL is found to be robust to different choices of the perturbation parameters. However, we found that applying high perturbations to node features (i.e. randomly dropping 50% to 70% of input features) and small perturbations of the graph structure (i.e. randomly dropping 10% to 20% of edges) results in stronger representations.

4.2. Results

We present the results of evaluating node representations using downstream multiclass node classification tasks in Table 2. We report average results over 50 runs of training followed by a logistic regression. Specifically, we use the mean classification accuracy on the test nodes for transductive tasks and the micro-averaged F1 score on the (unseen) test nodes for the inductive setting.

Transductive

Table 2: Classification accuracy on transductive tasks and micro-averaged F1 score on inductive tasks

We report the results of EP-B provided in [38] and [46], and also the results provided in [18]. To insure a fair comparison with the other methods, we report

1
2
3
4
5
6
7
8
9 the results of the standard implementation of GraphCL which was described in
10 the previous section. In particular we use a standard embedding size $P' = 512$.
11 We refer to the results by **GraphCL** in table 2. We also report **GraphCL***
12 which refers to the results that were achieved using the best parameters including
13
14
15
16 340 the best negative sampling strategy, choice of encoders and embedding size. For
17 example, we notice a 1% gain on the classification accuracy of Cora when using
18 a GCN encoder and sampling negative from the second order neighbors of the
19 current example. Moreover, we notice a surprising 0.2 gain on the F1 score on
20 PPI when increasing the embedding size to $P' = 2048$.
21
22

23 345 We see that the proposed GraphCL outperforms the previous state-of-the-art
24 by achieving the best classification accuracy over the three transductive tasks
25 and the best F1 score on inductive tasks. We note that, except for PPI dataset,
26 GraphCL achieves competitive performance with strong supervised baselines
27 without using label information. We assume that by maximizing agreement
28
29
30
31 350 between representations that share the same information but have independent
32 noise, GraphCL is able to learn representations that benefit from the richness
33 of information in the graph which compensate for the information provided by
34 the labels.
35
36
37

38 4.3. Ablation study

39
40 355 We report on a study to understand the effects of different parameters. All
41 experiments have been conducted using Cora dataset.
42
43

44 4.3.1. Effect of the number of negatives

45
46 Figure 2a shows the effect of the number of negatives on the accuracy of
47 the downstream classification task. We find that training a contrastive loss
48
49
50 360 with a small number of negatives leads to poor representations. However, our
51 experiments show that at a certain threshold increasing the number of negatives
52 does not improve the quality of the representations. Beyond that threshold the
53 variations of the classification accuracy seem to be due to the randomness of
54 the training procedure only. Since using a large number of negatives slows down
55
56
57
58

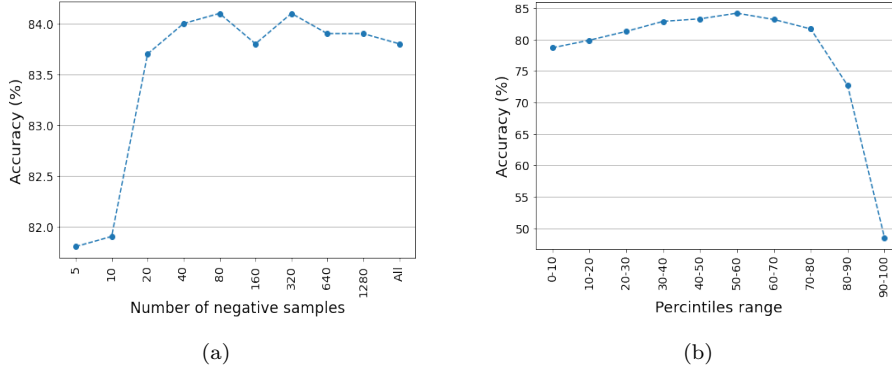

Figure 2: Classification accuracy on Cora dataset. (a) Effect of the number of negative examples. (b) Effect of the similarity between the current example and its corresponding negative samples.

the training and requires more computing power, our findings suggest that one has to properly choose the number of negatives to optimize for both the quality of the representations and the training efficiency.

4.3.2. Effect of feature similarity based negative sampling strategies

We next analyse the effect of hard negative samples on the quality of the learned representations. We first implement the feature similarity based negative sampling strategy described in section 3.2. We select negatives from a *ring* around the current example. This is done by varying the values of the percentiles ω_l and ω_k . Figure 2b show the accuracy of a linear classifier trained on the learned representation while varying the distance of the *ring* from the current example. We select negatives from a ring of diameter 10% (i.e. $\omega_l - \omega_k = 10\%$). The results confirm our intuition that hard negatives improve the quality of the representations. We notice that selecting only negatives that are too far from the current example leads to poor representations. In fact, if all negatives are easy to distinguish from the current example, there is no reason for the encoder to learn higher level features that can help to distinguish between the corresponding positive example and all the negatives. On the other hand, selecting negatives from nodes that are very similar to the current example worsens the

l-th order neighbors	Accuracy	Encoder	Accuracy
1	31.4 ± 1.2 %	MLP	66.1 %
2	84.6 ± 0.4%	Mean Pooling	83.6 %
3	80.8 ± 0.6 %	GCN	84.2 %

Table 3: Classification accuracy on Cora dataset. Effect of the number of hops between the current example and its corresponding negative samples.

Table 4: Classification accuracy on Cora dataset. Effect of the choice of the encoder

quality of the representations. This can be explained by the fact that negatives that are close to the current example are likely to belong to the same class and should rather be considered as positive examples. Training an encoder to push these examples away from the current example unsurprisingly leads to lower quality representations.

4.3.3. Effect of graph based negative sampling strategies

Graphs provide additional information about the examples. We aim at taking advantage of the graph structure to sample negative examples. Table 3 shows the average accuracy of 50 runs of training to learn nodes’ embeddings on top of which we apply a linear classifier. We sample negatives from the l -th order neighbors of the current example. Similarly to the results of the feature similarity based negative sampling strategy, we find that negatives that are at the right distance from the current example improve the quality of the learned representations. More specifically, we achieve the best performance when sampling negatives from the second order neighbors.

4.3.4. Training without negative samples

In the previous section, we have discussed the effect of negative sampling strategies on the quality of the learned representations by using them to linearly classify nodes on a multi-class classification downstream task. Here, we would like to see whether it is possible to learn meaningful representations by maximizing the similarities between the representations obtained from two views

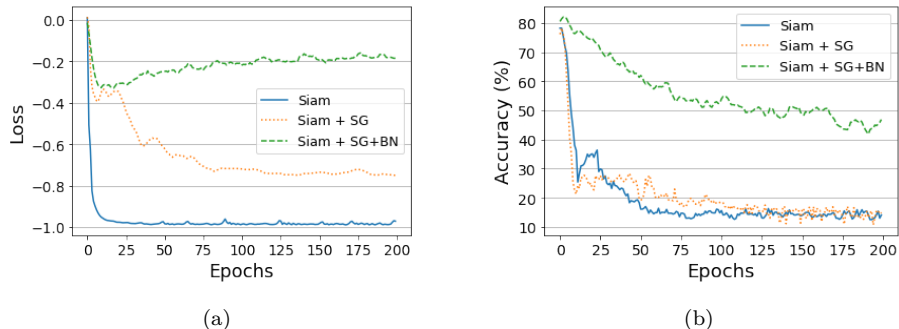

Figure 3: A comparison of Siamese NN trained *with* vs *without* stop-gradient and batch normalization. (a) Training loss across epochs. (b) Accuracy of a linear classifier trained on top of the representation on Cora dataset

of the same graph without the use of any negative examples. To do so, we train a Siamese neural network to minimize the negative cosine similarity loss in Eq. (4). We implement the stop-gradient strategy described in section 2.4 and apply batch normalization on the hidden layer of the prediction MLP head (see section 2.4). Both stop-gradient and batch normalization have been reported to prevent the collapsing to a single representation when applied to Siamese neural networks for visual representations [27, 28]. Figures 3a and 3b respectively show the loss and accuracy of training a Siamese neural network without neither batch normalization nor stop-gradient referred to as *Siam*, with stop-gradient but without batch normalization referred to as *Siam+SG*, and with both stop-gradient and batch normalization referred to as *Siam+SG+BN*.

We observe that when training without stop-gradient and batch normalization, the loss function quickly converges to the minimum possible value -1 . To verify that the cause is the collapsing to the single representation solution, we compute the standard deviation of all the representations which we found to be equal to zero for all features. We also notice that although adding stop-gradient and batch normalization prevent the collapsing to a single representation, the learned representations are still of low quality and perform much worse than the representations learned using negative samples.

5
6
7
8
9 **5. Discussion**

10
11 *5.1. Connection to mutual information*

12
13 The contrastive loss in Eq. (3) has been proposed as a lower bound estimator
14 of the mutual information. A formal proof given by [47] shows that:

15
16
17
$$I(h_q, h_q^+) \geq \log(N) - \mathcal{L}, \tag{12}$$

18
19 where N is the number of negative samples Q_q^- and $I(h_q, h_q^+)$ is the mutual
20 information between h_q and h_q^+ :

21
22
23
$$I(h_q, h_q^+) = \mathbb{E}_{(h_q, h_q^+) \sim p_{h_q, h_q^+}(\cdot)} \log \left[\frac{p(h_q, h_q^+)}{p(h_q)p(h_q^+)} \right] \tag{13}$$

24
25
26
27 425 where $p(h_q, h_q^+)$ is the joint distribution of h_q and h_q^+ , and $p(h_q)$ and $p(h_q^+)$ are
28 the corresponding marginals.
29

30
31 Therefore, given any N , minimizing the loss function \mathcal{L} also maximizes the
32 lower bound on the mutual information $I(h_q, h_q^+)$. We note however that it has
33 been shown that the bound in Eq. (12) can be not tight . Our experiments
34
35 430 suggest that contrastive methods' success highly depends on other parameter
36 designs, and so cannot be solely attributed to the properties of the mutual
37 information. This confirms the remark done in[48] where the bound in Eq. (12)
38 was seen not to be tight. More precisely, results in Table 4 emphasize the
39 impact of the choice of the encoder on the performance of the contrastive loss.
40
41 435 The ablation study that we conducted also highlights the effect of the negative
42 sampling strategy and the importance of hard negative examples for learning
43 powerful representations.
44
45
46
47

48
49 *5.2. Understanding contrastive learning through alignment and uniformity on*
50 *the hypersphere*

51
52 440 To better understand the behavior of GraphCL, we analyze it through the
53 perspective of uniformity and alignment that has been introduced in [49]. The
54 main idea behind the contrastive loss is to attracting positive pairs together in
55
56
57
58

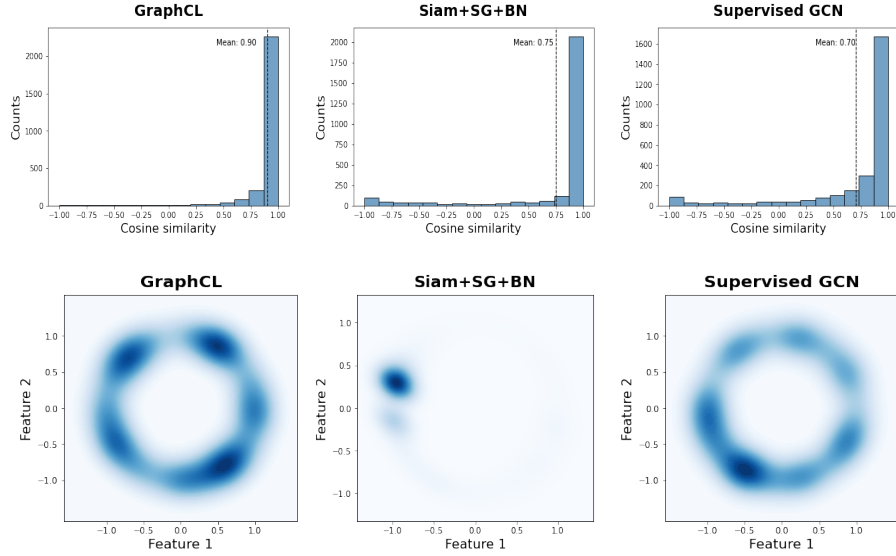

Figure 4: Representations of Cora dataset nodes on \mathbb{R}^2 using encoders trained with a contrastive loss (**Left plots**), a negative cosine similarity loss (**middle plots**) and a supervised cross entropy loss (**right plots**). Histograms of the cosine similarity between positive pairs (**Top**). Feature distributions in \mathbb{R}^2 using Gaussian kernel density estimation (**Bottom**).

the representation space while pushing away the corresponding negative examples from the current sample. Eq. (3) actually encourages the learned representations to obey the following properties:

- **Alignment:** Representations of augmented views should be consistent and invariant to noise.
- **Uniformity:** The learned representations should match a prior distribution of high entropy (the uniform distribution over the hypersphere) to preserve as much information of the data as possible.

We visualize the learned representations of Cora dataset nodes in \mathbb{R}^2 (i.e $P' = 2$) to compare the behavior of the following methods:

- **GraphCL:** An encoder trained with the standard implementation of GraphCL as described above.

- 455 • **Siam+SG+BN:** A siamese neural network encoder trained with the negative cosine similarity loss using stop-gradient and batch normalization techniques.
- **Supervised GCN:** An encoder and a linear classifier trained jointly with a supervised cross entropy loss.

460 All encoders are 2-layers GCNs that map nodes to normalized feature vectors of dimension two. Figure 4 summarizes the resulting distributions. GraphCL embeddings clearly display both properties. Positive pairs are more aligned than those learned using the negative cosine similarity and supervised loss with an average cosine similarity of 0.9 for GraphCL and 0.75 and 0.7 respectively for 465 the other methods. Representations of GraphCL are also evenly distributed on the hypersphere and exhibit the most uniform distribution.

It has been shown in [49] that both the alignment and uniformity properties are important in learning highly transferable features to downstream tasks. This contributes to the the success of GraphCL and may explain its ability to 470 outperform strong supervised baselines on nodes classification, especially on the transductive learning setup.

It is also worth noticing that although adding stop-gradient and batch normalization techniques to the training procedure of the negative cosine similarity loss (i.e. Siam+SG+BN in Figure 4) prevent the collapsing to the single 475 representation solution, the encoder fails to uniformly map the nodes’ representations across the hypersphere. This explains its results on the classification downstream task (see Figure 3b).

5.3. Computational and model complexity

Last we discuss the computational and model complexity of GraphCL. Let 480 $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be a graph and $N = |\mathcal{V}|$ the total number of nodes in the graph. Moreover, let L be the number of layers, M the minibatch size and R the number of neighbors being sampled for each node in the inductive setting. We

1
 2
 3
 4
 5
 6
 7
 8
 9 assume for simplicity that the dimension of the nodes' hidden features is con-
 10 stant and denote it as P' . The computational complexity and space complexity
 11 of GraphCL depend on the choice of the encoder. We use the same encoder
 12 485 of GraphCL depend on the choice of the encoder. We use the same encoder
 13 for the two branches (i.e. each of the subgraphs). For the transductive learn-
 14 ing setup, the computational and space complexity are linear with respect to
 15 the number of nodes and are respectively $\mathcal{O}(LNP'^2)$ and $\mathcal{O}(LNP' + KP'^2)$.
 16 For the inductive learning, we use a sub-sampling strategy to load the graphs
 17 into memory; the computational complexity is then $\mathcal{O}(R^L NP'^2)$ and the space
 18 490 complexity is $\mathcal{O}(MR^L P' + LP'^2)$. The computational complexity is linear with
 19 respect to the number of nodes. Both the number of layers L and the number
 20 of sampled neighbors R are fixed and user-specified. The space complexity is
 21 linear with respect to the minibatch size M . The sampling strategy sacrifices
 22 495 time efficiency to save memory which is necessary for very large graphs.
 23

 25
 26
 27
 28
 29
 30

31 6. Conclusion

32
 33 We introduced GraphCL, a general framework for self-supervised learning of
 34 nodes' representations. The key idea of our approach is to maximize agreement
 35 between two representations of the same node. The representations are gener-
 36 ated by injecting random perturbations to the graph structure and nodes' intrinsic
 37 500 features. We have conducted a number of experiments on both transductive
 38 and inductive learning tasks. Experimental results show that GraphCL outper-
 39 forms state-of-the-art unsupervised baselines on nodes' classification tasks and
 40 is competitive with supervised baselines. We further investigated different neg-
 41 ative sampling strategies including training with a similarity based loss without
 42 505 contrasting with negative samples and propose a graph based negative sampling
 43 strategy. In the future, we will investigate the potential of our approach in learn-
 44 ing graphs' representations that are robust to adversarial attacks on the graph
 45 data and explore the reasons of the low quality of nodes' representations when
 46 training a siamese neural network without negative samples.
